

ANATOMY OF THE FORESKIN

The Human Foreskin contains significantly more than half of all the sensory tissue on the penis. What's more is that the remaining sensory tissue does not function properly after HUFO's removal.

Below you will find the four major anatomical parts of the foreskin with their description.

THE FRENULUM

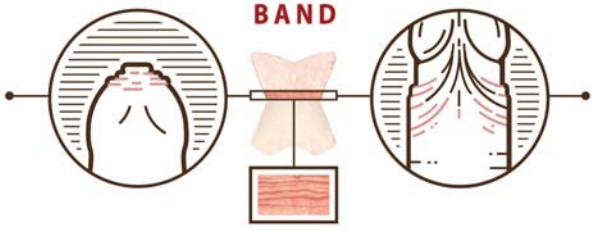

The highly erogenous V-shaped tethering structure on the underside of the penis. The frenulum connects the ridged band (read below) to the glans. Frenulums are also found underneath your lips and tongue.

INNER FORESKIN

Smooth mucosal tissue much like the inside of your mouth, the inner foreskin is densely nerve-packed and designed by nature to stimulate the head, as well as feel slight variations in pressure, stretching, subtle variations in temperature, and fine gradations in texture.

RIDGED BAND

Like the skin of the lips, forming transition from inner to outer mucosa, the ridged band is the primary erogenous zone of the body, loaded with fine-touch nerves. The band is equipped with soft ridges designed to stimulate the male head as well as the female inner labia and G-spot.

OUTER FORESKIN

Essential continuation of the shaft skin, the outer foreskin keeps the head protected and sensitive so it is ever-ready to respond to stimuli. It also facilitates intercourse and mitigates friction with a natural glidng motion

By adulthood, the inner and outer foreskin surface area varies widely, from 18 to 90 cm^2 of tissue[1], or 3 to 14 in^2. Typical neonatal circumcisions remove what would become approximately 50% of the mean penile shaft skin length by adulthood[2].
